Cox proportional hazards model

- Cox proportional hazard regression assesses the relationship between a right-censored, time-to-event outcome and multiple predictors:
 - categorical variables (e.g., treatment groups)
 - continuous variables

$$log(HR(x_i)) = log \frac{h(t|x_i)}{h_0(t)} = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + ... + \beta_p x_{pi}$$

- $HR(x_i)$ is the hazard of patient i relative to baseline
- $h(t|x_i)$ is the time-dependent hazard function h(t) for patient i
- $h_0(t)$ is the baseline hazard function, and is the negative of the slope of the $S_0(t)$, the baseline survival function.

Caveats and Assumptions

- Categories with no events
 - can occur when the group is small or its risk is low
 - HRs with respect to such a reference group are infinite
 - hypothesis tests and CIs are difficult / impossible to interpret
- Assumptions of Cox PH model
 - Constant hazard ratio over time (proportional hazards)
 - Linear association between log(HR) and predictors (log-linearity) / multiplicative relationship between hazard and predictors
 - Independence of survival times between individuals in the sample
 - Uninformative censoring: a censored participant is the same as an uncensored participant with the same covariates at still in the risk set after that time

Residuals analysis

- Residuals are used to investigate the lack of fit of a model to a given subject.
- For Cox regression, there's no easy analog to the usual "observed minus predicted" residual

Propensity score analysis

Martingale residuals

- censoring variable c_i (1 if event, 0 if censored) minus the estimated cumulative hazard function $H(t_i, X_i, \beta_i)$ (1 survival function)
 - E.g., for a subject censored at 1 year ($c_i = 0$), whose predicted cumulative hazard at 1 year was 30%, Martingale = 0 0.30 = -0.30.
 - E.g. for a subject who had an event at 6 months, and whose predicted cumulative hazard at 6 months was 80%, Margingale = 1 0.8 = 0.2.
- Problem: not symmetrically distributed, even when model fits the data well

Deviance residuals in simulated data

- Deviance residuals are scaled Martingale residuals
- Should be more symmetrically distributed about zero?
- Observations with large deviance residuals are poorly predicted by the model

Propensity score analysis

Schoenfeld residuals

- technical definition: contribution of a covariate at each event time to the partial derivative of the log-likelihood
- intuitive interpretation: the observed minus the expected values of the covariates at each event time.
- a random (unsystematic) pattern across event times gives evidence the covariate effect is not changing with respect to time
- If it is systematic, it suggests that as time passes, the covariate effect is changing.

Propensity score analysis

Schoenfeld test for proportional hazards

- Tests correlation between scaled Schoenfeld residuals and time
- Equivalent to fitting a simple linear regression model with time as the predictor and residuals as the outcome
- Parametric analog of smoothing the residuals against time using LOWESS
- If the hazard ratio is constant, correlation should be zero.
 - Positive values of the correlation suggest that the log-hazard ratio increases with time.

What are tests for trend?

- For models including an ordinal variable
- Such as PBC stage (1, 2, 3, 4), age category, ...
 - Is there a linear / quadratic / cubic relationship between coefficients and their order?
 - Test by LRT or Wald Test

Stages 2, 3, 4 (1=ref)

How to predict survival from a Cox model?

- The Cox model is a *relative* risk model
 - only predicts relative risks between pairs of subjects
- Key is to calculate the overall S(t), then multiply it by the relative hazard for the specific covariate pattern.
- In this example we plot the baseline survival for all stages together, then for stages 1-4 separately.

Propensity score analysis

What is stratification?

- relevant to all kinds of regression, not just survival analysis
- when analysis is separated into groups or strata
 - must have an adequate number of events in each stratum (at least 5 to 7)
 - can be used to adjust for variables with strong impact on survival
 - can help solve proportional hazards violations
- Strata have different baseline hazards
- Coefficients / Hazard Ratios are calculated within stratum then combined.
- Vittinghoff 6.3.2

How to stratify Example - in R, strata() can be added to any model

```
mycox <- coxph(Surv(time, os) ~ trt + strata(stage),</pre>
                data = pbc.os)
summary(mycox)
```

```
## Call:
## coxph(formula = Surv(time, os) ~ trt + strata(stage), data = ;
##
##
    n= 312, number of events= 125
##
##
         coef exp(coef) se(coef) z Pr(>|z|)
## trt -0.1063
                 0.8992 0.1814 -0.586
                                           0.558
##
      exp(coef) exp(-coef) lower .95 upper .95
##
```

Stratification

Competing Risks Data

Propensity score analysis

What are competing risks?

- Example from Vittinghoff 6.5: The MrOS study (Orwoll et al. 2005) followed men over 65 to examine predictors of bone fracture and low BMD (subclinical bone loss)
- At end of study participants had:
 - developed fracture (outcome of interest),
 - remained alive without fracture (incomplete follow-up), or
 - died prior to fracture (incomplete follow-up)

Orwoll, E. et al. (2005). Design and baseline characteristics of the osteoporotic fractures in men (MrOS) study–a large observational study of the determinants of fracture in older men. Contemporary Clinical Trials, 26(5), 569–585.

Competing Risks Data

Propensity score analysis

Why not treat died prior to fracture and alive without fracture as censored?

- Recall the independent censoring assumption (Vittinghoff 6.6.4):
 - censored people are similar to those who remain at risk in terms of developing the event of interest;
 - censoring is independent of the event of interest.
 - For patients who died this assumption is highly suspect

Competing Risks Data

Propensity score analysis

Reasons for right censored data

- Cut-off date of analysis (administrative censoring):
 - Censoring usually independent
- Loss to follow-up
 - Independence may be problematic if sicker individuals discontinue participant in study (lack of energy, too ill, return to home country)
 - or if healthier individuals discontinue participation (don't feel the need to continue, start new life in other country)
- Competing risks:
 - Often informative.
 - In competing risks analysis, independence between competing risks is not required

Competing Risks Data

Propensity score analysis

Very brief summary of competing risk methods

- 1-to-1 mapping between hazard and cumulative incidence function is lost in competing risks
- Standard Kaplan-Meier estimator is biased for competing risks data
 - Aalen-Johansen estimator is better choice
- Gary's test is analogous to log-rank test
- cause-specific standard Cox PH model might be useful for prognostic (causal) testing, but not estimating a population Hazard Ratio

Propensity score analysis

What is propensity score analysis?

 an alternative to multivariate regression to control for hypothesized confounders in observational studies:

outcome ~ exposure + counfounder1 + confounder2

- a stratification approach that is more practical than stratifying on multiple hypothesized confounders
- an approach to summarizing many covariates into a single score
- a convenient approach to controlling for many hypothesized confounders

Predictions for specific covariate patterns

Stratification

Competing Risks Data

Propensity score analysis

Propensity score approach to correction for confounders

• *Step 1*: fit the propensity score model (no outcome) that predicts propensity for exposure based on confounders:

exposure ~ counfounder1 + confounder2

- Step 2: use propensity predictions to match or stratify participants with similar propensity (for example, stratifying on quintiles of propensity)
- *Step 3*: check adequacy of matching or stratification, ie by comparing attributes of matched participants
- Step 4: test hypothesis among matched participants:

outcome ~ exposure
